Abstract
For $m \geq 4$ even, the duals of $p$-ary codes, for any prime $p$, from adjacency matrices for the $m$-ary 2-cube $Q_2^m$ are shown to have subcodes with parameters $[m^2, 2m - 2, m]$ for which minimal PD-sets of size $\frac{m^2}{2}$ are constructed, hence attaining the full error-correction capabilities of the code, and, as such, the most efficient sets for full permutation decoding.

Mathematics Subject Classification 05C50 · 94B05

1 Introduction

In [14] binary codes generated by the row span of adjacency matrices of the graphs from the $m$-ary $n$-cube $Q_n^m$ with adjacency defined by the Lee metric, were studied, and some notable results were obtained when $n = 2$ and $m$ is odd, in which case the codes are LCD. In particular, minimal $s$-PD-sets were obtained (i.e. of size $s + 1$) for $s \leq t - 1$, where $t$ is the error correcting capability of the code. Such sets are as efficient in decoding as is possible for permutation decoding, so it is useful to find them, in particular to find them up to $s = t$, for the codes for which that is possible. Here we look at the $p$-ary codes for $n = 2$ and $m \geq 4$ even, and any prime $p$, and find subcodes of $C_p(Q_2^m)$ for which PD-sets of minimal size $t + 1$ are found.

We follow the standard definition of the graphs, known as Lee graphs, as in, for example [5]: for $m, n \geq 2$ positive integers, and $R = \{0, 1, \ldots, m-1\}$ with addition and multiplication as in the ring of integers modulo $m$, $\mathbb{Z}_m$, or possibly the field $\mathbb{F}_m$ if $m$ is a prime power, the graph $\Gamma = (V, E)$ on $Q_n^m$, has $V = R^n$, the set of $n$-tuples with entries in $R$, with adjacency defined by $x = (x_0, x_1, \ldots, x_{n-1})$ adjacent to $y = (y_0, y_1, \ldots, y_{n-1})$ if there exists an $i$, $0 \leq i \leq n-1$, such that $x_i - y_i \equiv \pm 1 \pmod{m}$ and $x_j = y_j$ for all $j \neq i$. It follows that $\Gamma$ is regular of degree $2n$.

In this study we examine specific subcodes of the dual of the $p$-ary codes from graphs when $n = 2$ and $m \geq 4$ is even. This follows work done in [14] for which the main results were for binary codes when $m \geq 5$ is odd, specifically for $Q_2^m$. Some of the results from that paper generalize immediately to the $p$-ary case.

Since for $m = 2, 3$ the graph is the Hamming graph, the codes of which have been widely studied (see [6–9, 15], for example) we take $m \geq 4$.

A summary of our main result is:

**Theorem 1** Let $\Gamma = Q_n^m$ where $m \geq 4$ is even, and let $C = C_P(\Gamma)$, where $p$ is any prime. Then $C^\perp$ contains a subcode $D$ of parameters $[m^2, 2m - 2, m]_p$ for which the nested set 

$$S = \{\tau_{<2i,0>} \mid 0 \leq i \leq s\}$$

of automorphisms is an $s$-PD-set of minimal size $s+1$ for the code $D$, for $2 \leq s \leq t = \frac{m}{2} - 1$ with information set $\mathcal{I}$ where 

$$\mathcal{I} = \{<0, i> \mid i \in R\} \cup \{<1, i> \mid i \in R \setminus \{m - 2, m - 1\}\}.$$ 

here $\tau_{<a,b>} : <x, y> \mapsto <x + a, y + b>$. For $s = t = \frac{m}{2} - 1$, this is a minimal PD-set for full error correction for $D$.

Further, $D^\perp$ is an $[m^2, m^2 - 2m + 2, 2]_p$ code, and $D$ is LCD if $p \nmid m$.

The code $D$ is described in Proposition 1, and the rest of the proof of the theorem is in Proposition 2. These follow after Sect. 2 giving the terminology and background.

## 2 Background concepts and terminology

The notation for codes and codes from graphs is as in [1]. For an incidence structure $D = (\mathcal{P}, \mathcal{B}, \mathcal{J})$, with point set $\mathcal{P}$, block set $\mathcal{B}$ and incidence $\mathcal{J}$, the **code** $C_P(D) = C_q(D)$ of $D$ over the finite field $F = \mathbb{F}_q$ is the space spanned by the incidence vectors of the blocks over $F$. If $Q \subseteq \mathcal{P}$, then the **incidence vector** of $Q$ is written $v^Q$, or $v^x$ if $Q = \{x\}$. For any $w \in F^P$ and $P \in \mathcal{P}$, $w(P)$ denotes the value of $w$ at $P$.

The codes here are **linear codes**, and the notation $[n, k, d]_q$ will be used for a $q$-ary code $C$ of length $n$, dimension $k$, and minimum weight $d$, where the **weight** $wt(v)$
of a vector $v$ is the number of non-zero coordinate entries. Vectors in a code are also called \textbf{words}. For two vectors $u$, $v$ the \textbf{distance} $d(u, v)$ between them is $\text{wt}(u - v)$. The \textbf{support}, $\text{Supp}(v)$, of a vector $v$ is the set of coordinate positions where the entry in $v$ is non-zero. So $|\text{Supp}(v)| = \text{wt}(v)$. A \textbf{generator matrix} for $C$ is a $k \times n$ matrix made up of a basis for $C$, and the \textbf{dual} code $C^\perp$ is the orthogonal under the standard inner product $(, )$, i.e. $C^\perp = \{v \in F^n \mid (v, c) = 0 \text{ for all } c \in C\}$. The \textbf{hull}, $\text{Hull}(C)$, of a code $C$ is the self-orthogonal code $\text{Hull}(C) = C \cap C^\perp$. If $\text{Hull}(C) = \{0\}$ then $C$ and $C^\perp$ are \textbf{linear codes with complementary dual (LCD) codes}. A \textbf{check matrix} for $C$ is a generator matrix for $C^\perp$. The \textbf{all-one vector} will be denoted by $\mathbf{1}$, and is the vector with all entries equal to 1, and sometimes written $\mathbf{1}_m$ if it has length $m$. A \textbf{constant vector} is a non-zero vector in which all the non-zero entries are the same. Two linear codes are \textbf{isomorphic} (or permutation isomorphic) if they can be obtained from one another by permuting the coordinate positions. An \textbf{automorphism} of a code $C$ is an isomorphism from $C$ to $C$. The automorphism group will be denoted by $\text{Aut}(C)$, also called the permutation group of $C$, and denoted by $\text{PAut}(C)$ in [11].

The \textbf{graphs}, $\Gamma = (V, E)$ with vertex set $V$ and edge set $E$, discussed here are undirected with no loops. If $x, y \in V$ and $x$ and $y$ are adjacent, we write $x \sim y$, and $xy$ for the \textbf{edge} in $E$ that they define. The \textbf{set of neighbours} of $x \in V$ is denoted by $N(x)$, and the \textbf{valency of} $x$ is $|N(x)|$. $\Gamma$ is \textbf{regular} if all the vertices have the same valency.

An \textbf{adjacency matrix} $A = [a_{x,y}]$ for $\Gamma$ is a symmetric $|V| \times |V|$ matrix with rows and columns labelled by the vertices $x, y \in V$, and with $a_{x,y} = 1$ if $x \sim y$ in $\Gamma$, and $a_{x,y} = 0$ otherwise. The row corresponding to $x \in V$ in $A$ will be denoted by $r_x$. In the following, we may simply identify $r_x$ with the support of the row, so $r_x = \{y \mid x \sim y\} = N(x)$. The \textbf{code} over a field $F$ of $\Gamma$ will be the row span of an adjacency matrix $A$ for $\Gamma$, and written as $C_F(A)$, $C_F(\Gamma)$, or $C_p(A)$, $C_p(\Gamma)$, respectively, if $F = \mathbb{F}_p$.

### 2.1 The graphs $Q_n^m$

The graphs are defined in Sect. 1. For any $x \in R^n$, $x_i$ denotes the $i^{\text{th}}$ coordinate of $x$, for $0 \leq i \leq n - 1$.

For $a \in R^n$, $a = \langle a_0, a_1, \ldots, a_{n-1} \rangle$, the translation $\tau_a$ is the map defined on $x = \langle x_0, x_1, \ldots, x_{n-1} \rangle$ by

$$
\tau_a : x \mapsto \langle x_0 + a_0, x_1 + a_1, \ldots, x_{n-1} + a_{n-1} \rangle.
$$

(1)

If $\sigma_i \in S_n$ for $0 \leq i \leq n - 1$, then the map $\sigma$ is defined by

$$
\sigma^{-1} : x \mapsto \langle x_{\sigma_0}, x_{\sigma_1}, \ldots, x_{\tau_{n-1}} \rangle
$$

(2)

where the symmetric group $S_n$ is acting on the $n$ symbols $0, 1, \ldots, n - 1$.

For any $i$ such that $0 \leq i \leq n - 1$, the map $\mu_i$ is defined by

$$
\mu_i : x = \langle x_0, \ldots, x_{i-1}, x_i, x_{i+1}, \ldots \rangle \mapsto \langle x_0, \ldots, x_{i-1}, -x_i, x_{i+1}, \ldots \rangle,
$$

(3)

where $-x_i = m - x_i$. 

\begin{center}
\includegraphics[width=0.5\textwidth]{springer.png}
\end{center}
It is easy to verify that the translations \( \tau_a \) for \( a \in R^n \) and the permutations \( \sigma_i \), for all \( \sigma_i \), and \( \mu_i \) for all \( i \), are automorphisms of \( \Gamma \), and that \( \text{Aut}(\Gamma) \) is both vertex and edge transitive.

\( Q_n^m \) is the cartesian product \((Q_1^m)\square n\) of \( n \) copies of \( Q_1^m \). If \( A_{n,m} \) denotes the adjacency matrix for \( Q_n^m \) where the elements of \( R \) are labelled naturally, and the \( n \)-tuples likewise, we have \( A_{2,m} = A_{1,m} \otimes I_n + I_m \otimes A_{1,m} \) (Kronecker product) and \( A_{n,m} = A_{1,m} \otimes I_{m^{n-1}} + I_m \otimes A_{1,m} \). Since the matrix \( A_{1,m} \) will be \( m \times m \) of the form

\[
A_{1,m} = \begin{bmatrix}
0 & 1 & 0 & 0 & \cdots & 0 & 0 & 1 \\
1 & 0 & 1 & 0 & \cdots & 0 & 0 & 0 \\
0 & 1 & 0 & 1 & \cdots & 0 & 0 & 0 \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & \cdots & 1 & 0 & 1 \\
1 & 0 & 0 & 0 & \cdots & 0 & 1 & 0
\end{bmatrix},
\]

the matrix for \( A_{n,m} \) has the form

\[
A_{n,m} = \begin{bmatrix}
A_{n-1,m} & I & 0 & 0 & \cdots & 0 & I \\
I & A_{n-1,m} & I & 0 & \cdots & 0 & 0 \\
0 & I & A_{n-1,m} & I & \cdots & 0 & 0 \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & 0 & \cdots & I & A_{n-1,m} & I \\
I & 0 & 0 & 0 & \cdots & I & A_{n-1,m}
\end{bmatrix},
\]

(4)

where \( I \) is the \( m^{n-1} \times m^{n-1} \) identity matrix.

As was noted in [14, Corollary 3], the graphs \( Q_n^m \) are bipartite if \( m \) is even.

### 2.2 Permutation decoding

**Permutation decoding** involves finding a set of automorphisms of a code called a PD-set and was first developed by MacWilliams [18], and is described fully in MacWilliams and Sloane [19, Chapter 16, p. 513] and Huffman [11, Section 8]. In [12] and [17] the definition of PD-sets was extended to that of \( s \)-PD-sets for \( s \)-error-correction:

**Definition 1** If \( C \) is a \( t \)-error-correcting code with information set \( I \) and check set \( C \), then a **PD-set** for \( C \) is a set \( S \) of automorphisms of \( C \) which is such that every \( t \)-set of coordinate positions is moved by at least one member of \( S \) into the check positions \( C \).

For \( s \leq t \) an **\( s \)-PD-set** is a set \( S \) of automorphisms of \( C \) which is such that every \( s \)-set of coordinate positions is moved by at least one member of \( S \) into \( C \).

The algorithm for permutation decoding is as follows: for a \( t \)-error-correcting \([n,k,d]_q\) code \( C \) with check matrix \( H \) in standard form, so that a generator matrix can be written \( G = [I_k|A] \) where \( H = [-A^T|I_{n-k}] \), for some \( A \), and the first \( k \) coordinate positions correspond to the information symbols. Let \( S = \{g_1, \ldots, g_s\} \) be the PD-set.
Any vector \( v \) of length \( k \) is encoded as \( vG \). Suppose \( x \) is sent and \( y \) is received and at most \( t \) errors occur. Compute the syndromes \( H(y_g)T \) for \( i = 1, \ldots, s \) until an \( i \) is found such that the weight of this vector is \( t \) or less. Compute the codeword \( c \) that has the same information symbols as \( yg_i \) and decode \( y \) as \( c g_i^{-1} \).

Since this algorithm uses the PD-set as a sequence, the elements of the set \( S \) can be indexed by \( \{1, 2, \ldots, |S|\} \) so that elements that will correct a small number of errors occur first. Thus if nested \( s \)-PD-sets are found for all \( 1 < s \leq t \) then we can order \( S \) as follows: find an \( s \)-PD-set \( S_s \) for each \( 0 \leq s \leq t \) such that \( S_0 \subset S_1 \ldots \subset S_t \) and arrange the PD-set \( S \) as a sequence in this order:

\[
S = \{ S_0, (S_1 - S_0), (S_2 - S_1), \ldots, (S_t - S_{t-1}) \}.
\]

(Usually one takes \( S_0 = \{id\} \).

There is a bound on the minimum size that a PD-set \( S \) may have, due to Gordon [4], from a formula due to Schönheim [20], and quoted and proved in [11]:

**Result 1** If \( S \) is a PD-set for a \( t \)-error-correcting \( [n, k, d]_q \) code \( C \), and \( r = n - k \), then

\[
|S| \geq \left[ \frac{n}{r} \left[ \frac{n-1}{r-1} \left[ \cdots \left[ \frac{n-t+1}{r-t+1} \right] \cdots \right] \right] \right] = G(t).
\]

(5)

This result can be adapted to \( s \)-PD-sets for \( s \leq t \) by replacing \( t \) by \( s \) in the formula and \( G(s) \) for \( G(t) \).

We note the following result from [13, Lemma 1]:

**Result 2** If \( C \) is a \( t \)-error-correcting \( [n, k, d]_q \) code, \( 1 \leq s \leq t \), and \( S \) is an \( s \)-PD-set of size \( G(s) \) then \( G(s) \geq s + 1 \). If \( G(s) = s + 1 \) then \( s \leq \left\lfloor \frac{n}{k} \right\rfloor - 1 \).

Thus a set of size \( s + 1 \) to correct \( s \) errors is a *minimal set* for \( s \)-error correction. Such sets for some cases where \( G(t) = t + 1 \) have been found for sporadic codes, but an infinite class for binary codes with parameters \( [\left( \frac{n}{2} \right), n-1, n-1]_2 \) from the triangular graphs \( T(n) \) with \( n \) odd are found in [16]. Here \( t = \frac{n-3}{2} \) and PD-sets of size \( t + 1 = \frac{n-1}{2} \) were found. Minimal sets up to \( s = t - 1 \) have been found in various papers, for example:[10, 13].

A simple argument yields that the worst-case time complexity for the decoding algorithm using an \( s \)-PD-set of size \( z \) on a code of length \( n \) and dimension \( k \) is \( \mathcal{O}(nkz) \). Thus clearly the size \( z \) of the PD-set is important, and for any \( s \) this is at best \( s + 1 \), and thus \( t + 1 \) for full error correction.

### 3 The codes

Let \( \Gamma = (V, E) = Q^m_2 \), \( m \geq 4 \) even, \( R = \{0, 1, \ldots, m-1\} \), and \( C = C_p(\Gamma) \), \( p \) prime. Recall that row \( r_{<x,y>} \) denotes the row of an adjacency matrix for \( \Gamma \) corresponding to the vertex \(<x, y>\).
Lemma 1 For $m$ even, $m \geq 4$, and any prime $p$, let

$$S_1 = \{ <2i, 2i> | 0 \leq i \leq \frac{m}{2} - 1 \}, S_2 = \{ <2i + 1, 2i + 1> | 0 \leq i \leq \frac{m}{2} - 1 \}.$$ 

Then $w = \nu^{S_1} - \nu^{S_2} \in C^\perp$.

Proof We need to show that $(r_{<a,b>}, w) \equiv 0 \pmod{p}$ for every $<a, b> \in V$. Now the non-zero entries in $r_{<a,b>}$, i.e. the neighbours of $<a, b>$, are

$$\{ <a \pm 1, b >, <a, b \pm 1> \}.$$ 

Suppose $r_{<a,b>}$ meets $\text{Supp}(w) = S_1 \cup S_2 = \Lambda$. Without loss of generality, suppose $<a + 1, b> \in S_1$. Then $a + 1 = 2i$ and $b = 2i$, so $a = 2i - 1$ and $b - 1 = 2i - 1$, so $<a, b - 1> \in S_2$. Thus $(r_{<a,b>}, w) \equiv 0 \pmod{p}$. If $\text{Supp}(r_{<a,b>})$ does not meet $\Lambda$ then obviously $(r_{<a,b>}, w) \equiv 0 \pmod{p}$. This completes the proof.

Corollary 1 For $m$ even, $m \geq 4$, and any prime $p$, the minimum weight of $C^\perp$ is $m$.

Proof The lemma shows that there are words of weight $m$ so the minimum weight is at most $m$. Now the proof of [14, Lemma 3.5] generalizes to hold for any $p$ if it is modified to say that the minimum weight is at least $m$. The argument does not depend on the code being binary, or on $m$ being even or odd.

Similar to [14, Proposition 1] we have the following, where the automorphisms $\tau_{<a,b>}$ and $\mu_i$ are defined in Eqs. (1) and (3):

Proposition 1 For $m$ even and $m \geq 4$, and $p$ any prime, $F = (V, E) = \mathbb{Q}_2^n$, $C = C_p(\Gamma)$, let

$$S_1 = \{ <2i, 2i> | 0 \leq i \leq \frac{m}{2} - 1 \}, S_2 = \{ <2i + 1, 2i + 1> | 0 \leq i \leq \frac{m}{2} - 1 \}.$$ 

and $u_0 = \nu^{S_1} - \nu^{S_2}$. Write $u_i = u_0 \tau_{<i,0>}$ for $i \in R$, and $v_i = u_0 \tau_{<i,0>}, \mu_i = u_i \mu_0$ for $i \in R$. Let $U = \{ u_i, v_i \mid i \in R \}$. Then, over $\mathbb{F}_p$, $D = \langle U \rangle \subseteq C^\perp$ has dimension $2m - 2$, $D$ is a $[m^2, 2m - 2, m]_p$ code, and $D^\perp$ is a $[m^2, m^2 - 2m + 2, 2]_p$ code.

Further, if $p = 2$ then $D$ is self-orthogonal. For $p$ odd, if $p \nmid m$ then $\text{dim}(\text{Hull}(D)) = 2m - 6$.

For $m \geq 6$, the words in $U$ and their scalar multiples are the only words of weight $m$ in $D$.

Proof Clearly $|U| = 2m$ and each point $<a, b>$ is in the support of exactly one $u_i$, viz. $u_{a-b}$ and one $v_j$, viz. $v_{-a-b}$. Thus $\sum_{i \in R} u_i = \sum_{i \in R} v_i$, and the dimension of $D$ is at most $2m - 1$. Notice that $a - b$ and $-a - b$ are both even or both odd.

If we arrange the points in $V$ by first placing those with both entries even, then those with both entries odd, then those with the first entry even and the second odd, and finally those with the first entry odd and the second even, we see that $\sum_{i \text{ even}} u_i = \sum_{i \text{ even}} v_i$ and that likewise $\sum_{i \text{ odd}} u_i = \sum_{i \text{ odd}} v_i$. These
two relations are independent so $\dim(D) \leq 2m - 2$. Now proceed as in the proof of [14, Proposition 1]: suppose $w = \sum_{i=0}^{m-1} \alpha_i u_i + \sum_{i=0}^{m-1} \beta_i v_i = 0$. Then $w(<a, b>) = 0 = \alpha_{a-b} + \beta_{a-b}$, for all $a$, $b$, and taking $a = 0$ this shows that
\[ \alpha_i = -\beta_i \]
for all $i$, so $w = \sum_{i=0}^{m-1} \alpha_i (u_i - v_i) = 0$. Since $a-b = -\beta_{a-b} = \alpha_{a-b}$, we have $\alpha_i = \alpha_{i-c-2b}$ for all $c$, $b$ and hence $\alpha_i$ is constant over $a$ even and over $a$ odd. Thus $w = \alpha \sum_{i \text{ even}} (u_i - v_i) + \beta \sum_{i \text{ odd}} (u_i - v_i) = 0$. Each of these sums is already zero so we have no new relations and $\dim(D) = 2m - 2$.

For $\Hull(D)$, suppose $w = \sum_{\alpha \in R} \alpha_i u_i + \sum_{\beta \in R} \beta_i v_i \in D \cap D^\perp$. Then $(w, u_j) = (w, v_j) = 0$ for all $i \in R$. Clearly $(u_i, u_j) = (v_i, v_j) = m$ for all $i$, and $(u_i, u_j) = (v_i, v_j) = 0$ for all $i \neq j$. Suppose $<x, y> \in \Supp(u_i) \cap \Supp(v_j)$. Then it is easy to show that $<x + \frac{m}{2}, y + \frac{m}{2}> \subseteq \Supp(u_j) \cap \Supp(v_j)$, that the supports of $u_i$ and $v_j$ meet exactly twice, and that $i$ and $j$ are both even or both odd. Furthermore, if $<x, y> \in \Supp(u_i) \cap \Supp(v_j)$ then $<x + j, y \in \Supp(u_j) \cap \Supp(v_i)$. Conversely, if $i, j$ are both even or both odd, then $u_i$ and $v_j$ have precisely two points in common in their supports.

If $p = 2$ then clearly $D$ is self-orthogonal from what was said above, so $\Hull(D) = D$. For $p$ odd, taking first $p \nmid m$ and $i$ even, $w \in D \cap D^\perp$ as above, we have $(w, u_i) = ma_i + 2 \sum_{j \text{ even}} \beta_j = 0$, and thus, since $p \nmid m$, $a_i = a$ for all even $i$. Likewise $a_i = \beta_i$ for all odd $i$. Taking $(w, v_j) = 0$ gives $\beta_j = \gamma$ for $i$ even and $\beta_j = \delta$ for $i$ odd. Then since $ma_i + 2 \sum_{j \text{ even}} \beta_j = 0$ we have $ma_i + 2 \frac{m}{2} \gamma = 0$, so $a_i = -\gamma$ and similarly $\beta_i = -\delta$. Thus $w = \alpha \sum_{i \text{ even}} (u_i - v_i) + \beta \sum_{i \text{ odd}} (u_i - v_i)$. Since we showed above that each of the two sums is zero, we have also $w = 0$, proving that $D \cap D^\perp = \{0\}$.

Now take $p|m$. Again if $w = \sum_{\alpha \in R} \alpha_i u_i + \sum_{\beta \in R} \beta_i v_i \in D^\perp$ then $(w, u_j) = ma_j + 2 \sum_{j \text{ even}} \beta_j = 0$, and since $ma_j = 0$, we have $\sum_{j \text{ even}} \beta_j = 0$, and likewise $\sum_{j \text{ even}} a_j = 0, \sum_{j \text{ odd}} \beta_j = 0$, and $\sum_{j \text{ odd}} a_j = 0$. Thus, in particular, all the words $u_i - u_j$ and $v_i - v_j$ where $i$, $j$ are both even or both odd, will be in $D^\perp$. Thus $(\Hull(D), u_0, u_1, v_0, v_1) = D$ and hence $\dim(\Hull(D)) \geq 2m - 6$. To show it is exactly this, note that $(\Hull(D), u_0)$ contains all the $u_i$ for $i$ even, but not $u_i$ for $i$ odd, since if $u_i = au_0 + w$, where $w \in \Hull(D)$ then $u_i - au_0 \in \Hull(D)$ and thus $(u_i - au_0, v_j) = 0$, for all $i$ and this is not possible as $v_j$ cannot meet both $u_0$ or $u_0$. In a similar way one can argue that $v_0 \notin (\Hull(D), u_0, u_1)$, and then that $v_1 \notin (\Hull(D), u_0, u_1, v_0)$. Thus dim$(\Hull(D)) = 2m - 6$.

That $D$ has minimum weight $m$ follows from Corollary 1 since $D \subseteq C^\perp$ and does have words of weight $m$. That $D^\perp$ has minimum weight 2 follows as in the binary case, except that if $m \equiv 2 \pmod{4}$ then $<0, 0> + \frac{m}{2} \gamma \in D^\perp$, while if $m \equiv 0 \pmod{4}$, $<0, 0> - \frac{m}{2} \gamma \in D^\perp$.

To show that for $m \geq 6$ the words in $U$ and their scalar multiples are the only words of weight $m$, we can proceed as in the proof of [14, Lemma 3.5]. Thus suppose $w \in D$ has support $S$ and $|S| = m$. We use the fact $(w, u) = 0$ for all the weight-2 words in $D^\perp$, and $(w, r_X) = 0$ for all $X \in V$. Notice also that for any $<a, b> \in V$, $<a, b> \sim <x, y>$ if and only if $<a + m/2, b + m/2> \sim <x + m/2, y + m/2>$.

Taking $<0, 0> \in S$, we must also have $<\frac{m}{2}, \frac{m}{2} > \in S$, from the observation above. All the rows $r_X \ni <0, 0>$ must meet $S$ again at least once, so considering the four rows containing $<0, 0>$, we need to include $<1, 1>, <1, -1>, <1, 1>, <1, 1>$, or $<1, -1>, <1, -1, 1>$, to achieve this. Then also $<1 + m/2, 1 + m/2>, <1 + m/2, -1 + m/2> or <1 + m/2, -1 + m/2>, <1 + m/2, 1 + m/2>$.
must be included for the weight-2 vectors in $D^\perp$. This will cover the rows through $<\frac{m}{2}, \frac{m}{2}>$.

If $m = 6$ these six vertices give the support of $u_0$ if we make the first choice, and $v_0$ if we make the second. Without loss of generality, let us make the first choice, so we have $S = \text{Supp}(u_0)$. If $w$ is not a multiple of $u_0$ then we could produce a word of smaller weight in $D$. This proves the result for $m = 6$. Proceeding to $m \geq 8$, we need to consider the rows through $<1, 1>$ and we see that including $<2, 2> \sim <1, 1>$, and $<2 + \frac{m}{2}, 2 + \frac{m}{2}>$ is required. If $m = 8$ we have $u_0$ again.

We now proceed inductively, as in the proof of [14, Lemma 3.5] where at each stage we need to include a neighbour of the vertex $<i, i> \in S$ for smallest $i$ for which $<i + 1, i + 1>$ is not included. The steps are similar to the proof of [14, Lemma 3.5], except that in that lemma $m$ could be odd, and the code was binary.

This completes the proof for $m \geq 6$. For $m = 4$ there are more words of weight $4$, for all $p$. For example, from Magma [2, 3] computations, the word with support $\{<0, 0>, <2, 2>, <0, 2>, <2, 0>\}$ is in $D$, but clearly not in $\mathcal{U}$.

Extending the result obtained in Proposition 3 of [14], we have the following:

**Proposition 2** For $\Gamma = Q^m_2$ where $m \geq 4$ is even, $R = \{0, \ldots, m - 1\}$, and $D = \langle \mathcal{U} \rangle$ over $\mathbb{F}_p$, $p$ a prime, where $\mathcal{U}$ is as in Proposition 1:

1. the set
   \[
   \mathcal{I} = \{<0, i>| i \in R\} \cup \{<1, i>| i \in R \setminus \{m - 2, m - 1\}\}
   \] (6)
   is an information set for $D$.
2. For $s \leq \frac{m - 2}{2}$, the set of $s + 1$ automorphisms
   \[
   S = \{\tau_{<2i, 0>}| 0 \leq i \leq s\}
   \] (7)
   is an $s$-PD-set of minimal size $s + 1$ for the code $D$ with information set $\mathcal{I}$ as given in Eq. (6). For $s = \frac{m}{2} - 1$, the full error correction property of the code is attained.

**Proof** The proof follows the same lines as that of Lemma 4.1 and Proposition 3 of [14].

First we show that $\mathcal{I}$ is an information set. Use the notation of Proposition 1. Consider the generators of the code $D$, viz. $u_0, \ldots, u_{m-1}, v_0, \ldots, v_{m-1}$, and write them as rows of a $2m \times m^2$ generating matrix for $D$, but with the rows in the order

\[ u_0, u_{m-1}, u_{m-2}, \ldots, u_1, v_0, v_{m-1}, v_{m-2}, \ldots, v_1, \]

and columns in the natural order $<0, 0>, <0, 1>, \ldots, <m - 1, m - 1>$. We consider only the first $2m$ columns, from $<0, 0>$ to $<1, m - 1>$ as we know $D$ has dimension $2m - 2$. Then the non-zero entries in these columns are:

\[ u_0 \ni <0, 0>, - <1, 1>; \quad u_{m-1} \ni - <0, 1>, <1, 2>; \quad u_{m-2} \ni <0, 2>, - <1, 3> ; \quad \ldots ; \quad u_1 \ni - <0, m - 1>, <1, 0>; \quad v_0 \ni <0, 0>, - <1, m - 1>; \quad v_{m-1} \ni - <0, 1>, <1, 0>; \quad \ldots ; \quad v_1 \ni - <0, m - 1>, <1, m - 2>. \]
Now use the first $m$ rows, which have leading entries alternating ±1 at $<0,0>, ..., <0,m-1>$ to remove the similar leading entries in the second set of $m$ rows, with the new ordered rows $u_0, u_{m-1}, ..., u_1, v_0^* = v_0 - u_0, v_{m-1}^* = v_{m-1} - u_{m-1}, ..., v_1^* = v_1 - u_1$.

Consider now the lower $m$ rows starting with $v_0^*$, and columns starting at $<1,0>, ... <1,m-1>, - <1,0>, ..., - <1,2>, v_{m-2}^* \in - <1,1>, <1,3>, ..., v_1^* \in - <1,0>, v_1 \in 1, m - 2, >, - <1,0>$. Reorder these rows as $v_{m-1}^*, v_{m-2}^*, ..., v_1^*, v_0^*$. Now replace the row of $v_1^*$ by $v_1^{**} = v_1^* + v_{m-3}^* + v_{m-1}^*$ which is zero in all the columns of $<1,i>$, and replace $v_0^*$ by $v_0^{**} = v_0^* + v_{m-4}^* + v_{m-2}^*$ which is also zero in the columns of $<1,i>$. There are leading entries ±1 in the columns $<1,0>, ..., <1,m-2>$, and thus we have an information set, since we already know the dimension is $2m - 2$.

By Proposition 1, $D$ is an $[m^2, 2m - 2, m]$ code and can correct $t = \frac{m^2 - 2}{2}$ errors. It is quite straightforward to show that the bound $G(t)$ in Eq. (5) is $\frac{m^2}{2} = t + 1$. Result 2 tells us that if $G(s) = s + 1$ then $s \leq \frac{m^2}{2} - 1$ which is $\frac{m}{2} - 1 = t$ here. Thus we take $s \leq \frac{m^2}{2}$ and show that the set $S$ of Eq. (7) of size $s + 1$ will correct $s$ errors.

If all the $s$ errors are in $I$, then any non-identity element of $S$ will take them all into $C$, and if all the $s$ errors are in $C$ then the identity $\tau_{<0,0}>$ will keep all the errors in $C$. Since any number of errors in $I$ can be corrected by any non-identity element of $S$, we assume there are $s - 1$ errors in $C$ and one in $I$. If we prove our result for such a set it will follow for any smaller number.

Suppose the errors in $C$ occur at $e_r = <i_r,j_r>$ for $1 \leq r \leq s - 1$, with $e_0 \in I$ the error in $I$. So $1 \leq i_r \leq m - 1$ for $1 \leq r \leq s - 1$. Since $\tau_{<2,0>2}$ is $\tau_{<2,0>2}^*$, we see that the set of images of $i_r$ under the elements of $S$ are all distinct and all have the same parity. Thus any set of $s$ images $i_r + 2i$, for $1 \leq i \leq s$ can contain 0 or 1 only once. There are $s - 1$ points $e_r$, so considering the $s$ sets of images of these points under non-identity elements of $S$, i.e. $\{e_r^*_{<2,0>2} \mid 1 \leq r \leq s - 1\}$ for $1 \leq i \leq s$, there must be a value of $i$ such that neither 0 nor 1 is in that image, i.e. the points are all in $C$. This $\tau_{<2,0>2}$ will move the full set of $s$ error positions to $C$.

Thus $S$ is an $s$-PD-set for $s \leq t$ of $s + 1$ elements, and in particular, for $s = t$ we have a set of size $t + 1 = \frac{m}{2}$ for full error correction. Furthermore, the set is nested by the natural order.\[\square\]

Thus the full proof of Theorem 1 is complete.\[\square\]
